INTRODUCTION

Septicemia is a common cause of morbidity and mortality in neonates and children despite advanced measures for early diagnosis and treatment, introduction of new antimicrobial agents, considerable progress in hygiene, and aggressive enteral feeding. 1 Neonatal sepsis is defined as a clinical syndrome of septicemia presenting with systemic signs and symptoms of infection in the first four weeks of life.2 On the basis of time or postnatal age of onset, neonatal sepsis can be classified into Early onset neonatal sepsis (within 72 hours to 7 days of birth) and Late onset sepsis (7th day to 1 month of birth).3 Early onset infections are thought to be commonly transmitted vertically from mother to child. 7Late onset neonatal infections are primarily caused by bacteria thriving in external environment i.e. they are either Community or Hospital acquired, most-ly acquired from , from the hands of the care takers but may be acquired during delivery by vertical transmission from the moth-er.3,4 Septicemia in children in PICU is a common cause of morbidity and mortality. Most of the infections in PICU are nosocomial. The longer the stay, greater is the contact of patient with the healthcare personnel, higher are the chances of infection through exposure to environmental organisms and invasive procedures, which may end up in septicemia.

Risk factors for sepsis in PICU are prolonged central venous catheter use, receipt of extracorporeal membrane oxygenation, mechanical ventilation, dialysis and total parenteral nutrition. A wide variety of bacteria can cause septicemia in neonates and children and this bacteriological profile is constantly under change. The common gram positive organisms are Staphylococcus aureus, both Methicillin sensitive Staphylococcus aureus (MSSA) and Methicillin resistant Staphylococcus aureus (MRSA), Group B streptococcus, and Coagulase negative Staphylococcus (CoNS). Gram negative organisms are Escherichia coli, Klebsiella pneumoniae, Enterobacter sp, Acinetobacter baumannii, Pseudomonas aeruginosa, Listeria sp. E coli & Group B streptococci(GBS) most frequently cause EOS , being members of the maternal genitourinary tract which may ascend through birth canal to amniotic fluid either through intact amniotic membranes or after their rupture .2,5 Klebsiella sp, Enterobacter sp, Citrobacter sp, Pseudomonas sp., CoNS and Staphylococcus aureus, both Methicillin sensitive and resistant; are more common causes of Late onset septicemia.Bacteriological culture of the offending pathogen from blood sample of the patient remains the mainstay of diagnosis of septicemia. Both neonates and children are susceptible to infections leading to septicemia which makes the knowledge of bacteriological profile, its epidemiology in the region or hospital and monitoring of the same essential.2 The shortcomings of blood culture uch as low sensitivity and reporting delay of 24–72 hrs have been overcome in the last decade with the advent of automated continuous blood culture monitoring systems like BacTalert, ESP System etc.6 The present study was designed for isolation and identification of the causative bacterial organisms of septicemia in neonatal and paediatric ICU’s and selecting their antibiotic susceptibility pattern thus proving helpful in making a proper policy for rational prophylactic & therapeutic use of antibiotics in that hospital.

MATERIAL AND METHODS

The present study was conducted in the Department of Microbiology in collaboration with Department of Pediatrics, Sri Guru Ramdas Institute of Medical Sciences and Research, Amritsar after the approval of protocol by the Hospital Ethics Committee. The study design was prospective, observational and included 100 consecutive blood samples of suspected septicemic patients in NICU and PICU each over a period of one and a half year from October 2013 to March 2015. A detailed history was taken and also clinical and laboratory findings were noted.

2-3 ml of blood was withdrawn under strict aseptic precautions from the children preferably before the administration of antibiotic therapy. The samples were collected both in blood culture bottle containing Brain heart infusion broth and automated BacTalert bottles. The brain heart infusion bottles were incubated overnight at 37°C aerobically and sub cultured on blood and Mac Conkey agar on day 1, 2,3,5,7 & 10. The BacTalert bottles were placed in the wells of fully automated system for incubation and periodic reading was done. Those signalling positive were cultured on Blood and Mac Conkey’s agar. An incubation period of 7 days was allowed for the bottles in the automated system before reporting them negative. Depending upon the observation of Gram’s staining, specific biochemical tests were put up for the final identification. The antibiotic susceptibility testing of the isolates was done by Kirby- Bauer disk diffusion method on Mueller Hinton agar as per Clinical Laboratory Standards Institute (CLSI) guidelines. MRSA detection was done by putting Cefoxitin disc (30µg). Zone of inhibition of ≥22mm was considered susceptible while ≤21mm was labelled as MRSA as per CLSI.ESBL detection (Extended spectrum beta lactamase) was done in all isolates.
of E. coli & Klebsiella sp. by disc potentiation test using Ceftazidime (30µg) with and without clavulanic acid (10µg). A ≥5mm increase in zone diameter in ceftazidime+ clav- ulanic acid combination as compared to that of ceftazidime alone was labelled as an ESBL producer as per CLSI.Carbapenem resistant isolates of Acinetobacter spp and Pseudomonas spp tested for Metallo beta lactamase production by double disc synergy test using Meropenem (10µg) and EDTA. For Pseudomonas, an increase in zone of inhibition ≥7mm in meropenem+EDTA over Meropenem alone was taken as MBL positive. For Acinetobacter sp, the zone with the Meropenem and EDTA disc was ≥17mm for MBL positive and for MBL negative the inhibition zones of meropenem & EDTA were ≤14mm. The results were compiled, tabulated and analysed statistically to obtain valid conclusions.

**OBSERVATIONS**

Out of the total 200 consecutive blood samples of suspected septicemia patients from NICU and PICU, 71 (35.5%) patients had septicemia confirmed by positive bacterial cultures. NICU showed a higher number of isolates i.e. 41 (41%) followed by PICU, 30 (30%). In NICU, LOS (66%) was more common than EOS (34%). Males were more commonly affected than females. The mean gestational age of septicemic neonates was 34.07 ±3.13 weeks (mean ± SD) in NICU. Preterm neonates had a statistically significant higher rate of septicemia (82%) than the term neonates (17%). In PICU, septicemia was more frequently reported in children under 1 year (36.7%) however, NICU age had no influence over culture positivity here. Mean weight of septicemic neonates in this study was 1.78 ± 0.43 kg (mean± SD) although it didn’t influence culture positivity statistically. The most important risk factor of suspected septicemia in neonates in our study population was respiratory distress (41.5%), followed by premature rupture of membranes (34%) & meconium stained liquor (24.5%) as against CNS disease in PICU.

**Table no 3 AST of culture isolates in PICU:**
DISCUSSION

Septicemia, a life threatening emergency, is an important cause of morbidity and mortality in children especially neonates. It poses a great challenge to pediatricians all over the world especially in developing countries like India. In our study the incidence of microbiologically detected septicemia by BacTalert and conventional methods in clinically suspected patients in NICU was 41% (41/100). This was consistent with study by Mustafa and Ahmed in NICU in Hyderabad with a similar 44.2%, Shrestha R et al (41.3%) in Nepal, in Tanzania by Kayange et al (39%), in Korea by Shim et al (43.2%). Repeated subcultures increase the chances of isolation of the organisms from blood cultures, as was seen in this study. 7, 8, 9, 10

The incidence of septicemia in PICU in our study was 30%. Similar result was obtained by Tsering et al in Sikkim with 36% and Becerra et al (a developing country) with 20%. Naher et al in Dhaka with 53%.11,12

The blood culture yield by using the BacTalert system in the current study in the incidence of neonatal sepsis by BacTalert and conventional methods in clinically suspected patients in NICU was 41% (41/100). This was consistent with study by Mustafa and Ahmed in NICU in Hyderabad with a similar 44.2%, Shrestha R et al (41.3%) in Nepal, in Tanzania by Kayange et al (39%), in Korea by Shim et al (43.2%). Repeated subcultures increase the chances of isolation of the organisms from blood cultures, as was seen in this study. 7, 8, 9, 10

The 66% blood culture positivity in neonates with Late Onset Sepsis may no longer be effective as the sensitivity of Klebsiella and E.coli to these drugs was low. E.coli and Klebsiella sp showed a high resistance of 75% to Third generation cephalosporins, of 62.5% to fluoroquinolones and 87.5% to aminoglycosides. The resistance of gram negatives to third generation cephalosporins (80.9%) was high in agreement with Movahedian, Auranzeb et al.15,21 with 81% and 71.6% respectively. The high resistance of these organisms to third generation cephalosporins can be attributed to the frequent production of ESBL by these organisms. Different rates of ESBL production have been reported by various authors.22,23

A higher number of Staphylococcus aureus strains (11/18) i.e.61% were methicillin- resistant. This reflects the high prevalence of MRSA due to colonization of neonates hospitalized in NICU. 17 In our study as well, it was the most common cause of LOS. (44%) in NICU and was also the notorious pathogen caus- ing septicemia in PICU (40%). MRSA has been reported by Foglia as one of the leading causes of nosocomial pneumonias esp ven- tilator associated in PICUs, as also found in our study. 18

Staphylococcus aureus of the current study was totally susceptible to Vancomycin i.e.100% both in NICU and PICU followed closely by Piperacillin–tazobactam. This was in concordance with study by Sharma and Srinivasa et al.19,20 Routinely used antibiotic like Amoxicillin showed a better sensitivity in PICU (73.3%) than NICU (50%).

CONCLUSION

Pediatric septicemia can be prevented to a large extent by strict adherence by healthcare workers to hygienic guidelines especially hand washing. Screening of healthcare providers for MRSA carriage should be done and those found to be colonized should be treated. An antibiotic policy with involvement of microbiologists should be implemented in the hospital to prevent the indiscriminate use of antibiotics thereby improving clinical outcome decreasing economic burden on the patient’s family, the hospital and the country.
